Overview

Overview

- 2 k-Nearest-Neighbor
- 3 Performance metrics
- 4 Cross Validation
- **5** References

Overview

- **Parametric** methods need to **find parameters** from data and then use the inferred parameters to decide on new data points
  - · Learning: finding parameters from data
  - e.g., Linear regression, Logistic regression
- Non-parametric methods
  - Training examples are explicitly used
  - Training phase is not required
  - e.g., k-Nearest neighbors (kNN)
- Both supervised and unsupervised learning can be categorized into parametric and non-parametric methods

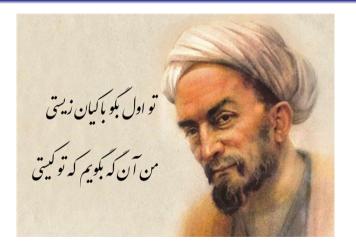

# Non-parametric learners

- Memory-based or Instance-based learners
  - lazy learning: (almost) all the work at the test time
- Generic description:
  - Memorize training  $(x^{(1)}, y^{(1)}), \dots, (x^{(n)}, y^{(n)})$
  - Given test *x* predict:  $\hat{y} = f(x; x^{(1)}, y^{(1)}, \dots, x^{(n)}, y^{(n)})$
- f is typically expressed in terms of the similarity of the test samples x to the training samples  $x^{(1)}, \dots, x^{(n)}$
- kNN is an instance-based learner

- Overview
- 2 k-Nearest-Neighbor
- 3 Performance metrics
- 4 Cross Validation

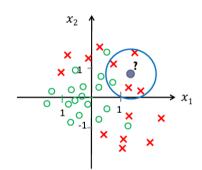

# kNN concept

• First, tell me who you have lived with, Then, I will tell you who you are.

### **kNN**

- K-NN classifier:  $k \ge 1$  nearest neighbors
  - Label for x predicted by majority voting among its k - NN
- $k = 5, x = [x_1, x_2]$

### kNN classifier

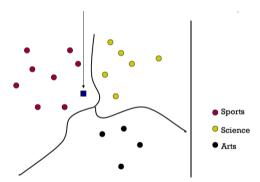

- Given
  - Training data  $\{(x^{(1)}, y^{(1)}), \dots, (x^{(n)}, y^{(n)})\}$  are simply stored.
- To classify *x*:
  - Find k nearest training samples to x
  - Out of these k samples, identify the number of samples  $k_j$  belonging to class  $C_j$  (j = 1, ..., C).
  - Assign *x* to the class  $C_{j^*}$  where  $j^* = \underset{j=1,...,c}{\operatorname{argmax}} k_j$
- It can be considered as a **discriminative** method.

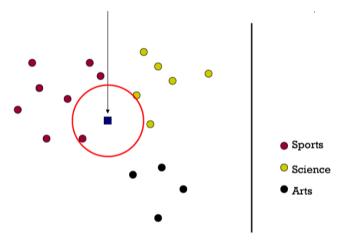

### kNN classifier cont.

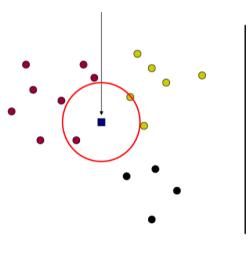

- With kNN we can obtain non-linear decision surfaces unlike the previous methods (linear and logistic regression)
- But note that this method could be prone to outliers or noisy data especially if:
  - We have small dataset
  - Our data is low-dimensional
  - We use a **small value of k** (like k = 1 is only determined by the nearest neighbor and could be misleading in many test cases.

# kNN example

• We want to classify a new document and put it into one of three categories by studying its neighbor samples

Figures for this example were adapted from E. Xing, "Theory of classification and nonparametric classifier." Lecture notes

### Voronoi tessellation

- Voronoi tessellation:
  - Each cell consists of all points closer to a given training point than to any other training points
  - All points in a cell are labeled by the category of the corresponding training point

[Duda, Hurt, and Strok's Book]

### Voronoi tessellation

• 1NN plot is a Voronoi tessellation

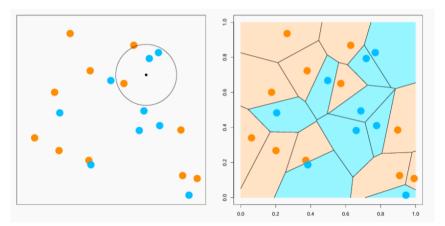

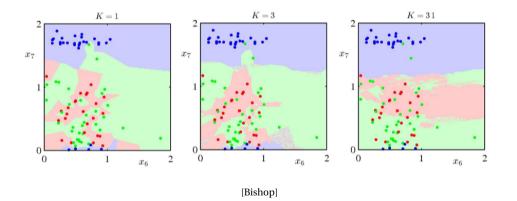

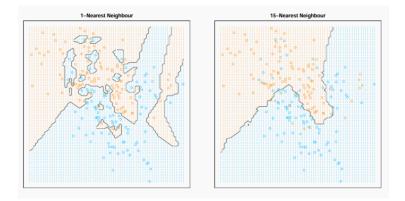

Figure adapted from R. Zhu, "Stat 542: Statistical learning - k-nearest neighbor and the bias-variancetrade-off." Lecture notes.

### Effect of k

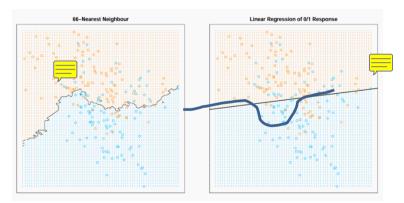

### Effect of k cont.

• compare k = 1 with k = 15

# Model complexity

- As we further increase *k*, the model tends to be less complex.
- Compare 66*NN* with a linear model that uses only 3 parameters:

Figures were adapted from R. Zhu, "Stat 542: Statistical learning - k-nearest neighbor and the bias-variancetrade-off." Lecture notes a continuous continu

### Instance-based learner

- Main things to construct an instance-based learner:
  - A distance metric
  - Number of nearest neighbors of the test data that we look at
  - A weighting function (optional)
  - How to find the output based on neighbors?

### Distance measures

Euclidean distance

$$d(x, x') = \sqrt[2]{\|x - x'\|_2^2} = \sqrt[2]{(x_1 - x_1')^2 + \dots + (x_d - x_d')^2}$$

- Distance learning methods for this purpose
  - Weighted Euclidean distance

$$d_w(x, x') = \sqrt[2]{w_1(x_1 - x'_1)^2 + \dots + w_d(x_d - x'_d)^2}$$

### Distance measures cont.

Minkowski distance

$$d(x, x') = \left(\sum_{i=1}^{n} |x_i - x'_i|^p\right)^{\frac{1}{p}}$$

Performance metrics

- for  $p \ge 1$  is a distance metric
- As you can see Minkowski distance with p = 2 is the same as Euclidean distance
- Minkowski distance is the same as  $L^p$  norm of (x x')
- Remember  $L^p$  norm from linear algebra:

$$||x||_p = \sqrt[p]{(|x_1|^p + \dots + |x_n|^p)}$$

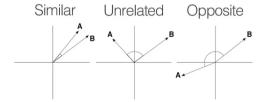

Some famous 
$$L^p$$
 norms 
$$\begin{cases} \|x\|_1 &= \sum_{i=1}^n |x_i| \\ \|x\|_2 &= \sqrt{x_1^2 + \dots + x_n^2} \\ \|x\|_\infty &= \max\{|x_1|, |x_2|, \dots, |x_n|\} \end{cases}$$

### Distance measures cont.

• Cosine distance (angle)

$$d(x, x') = 1 - \text{cosine similarity}(x, x')$$

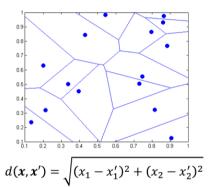

Where, cosine similarity(
$$x, x'$$
) =  $\frac{x \cdot x'}{\|x\|_2 \|x'\|_2} = \frac{\sum_{i=1}^d x_i x'_i}{\sqrt{\sum_{i=1}^d x_i^2} \sqrt{\sum_{i=1}^d x'_i^2}}$ 

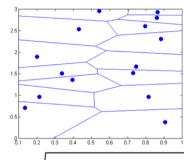

Example of angle difference for cosine similarity

Figure adapted from https://medium.com/@milana.shxanukova15/cosine-distance-and-cosine-similarity=a5da0e4d9ded

### Effect of distance measure

$$d(\mathbf{x}, \mathbf{x}') = \sqrt{(x_1 - x_1')^2 + 3(x_2 - x_2')^2}$$

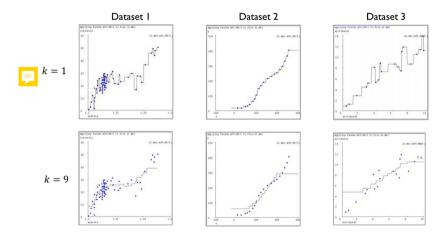

# kNN regression

• Let  $x'^{(1)}, ..., x'^{(k)}$  be the k nearest neighbors of x and  $y'^{(1)}, ..., y'^{(k)}$  be their labels.

$$\hat{y} = \frac{1}{k} \sum_{j=1}^{k} y'^{(j)}$$

- Some problems of kNN regression for fitting functions:
  - Discontinuities in the estimated function
  - 1NN: noise-fitting problem
  - kNN (k > 1) smoothes away noise, but there could be other issues (e.g, flats the ends)

# kNN regression cont.

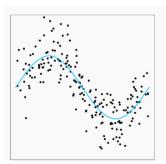

[Figs. have been adopted from Andrew Moore's tutorial on "Instance-based learning"]

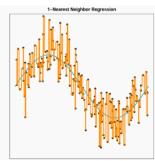

## kNN regression: example

• Suppose we have a dataset with only 1 feature from uniform  $[0, 2\pi]$ . The true model is:

$$Y = 2\sin(X) + \epsilon$$

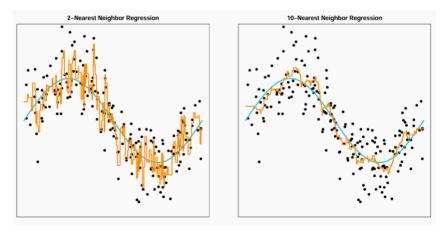

- Where  $\epsilon$  is the standard normal error.
- First we simulate 200 observations, and see the model for k=1

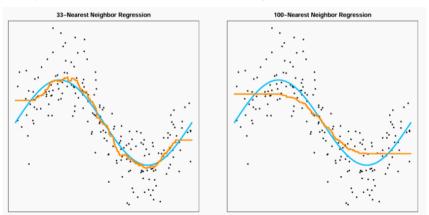

### kNN regression: example

• Now for k = 2 and k = 10

### kNN regression: example

• As you can see the model becomes smoother as *k* increases. However, this eventually deviates from the truth if *k* is too large

Figures were adapted from R. Zhu, "Stat 542: Statistical learning - k-nearest neighbor and the bias-variancetrade-off." Lecture notes.

# Accuracy in classification problems

- Accuracy is one of the simplest and most commonly used performance metrics.
- It is defined as the ratio of correctly predicted instances to the total instances:

$$Accuracy = \frac{True\ Positives + True\ Negatives}{Total\ Samples}$$

Performance metrics

• However, accuracy alone can be misleading, especially with imbalanced datasets.

# Example: cancer detection problem

- Imagine a dataset with 1000 patients:
  - Only 10 have cancer (**positive class**).
  - 990 do not have cancer (**negative class**).
- A classifier predicts that no one has cancer (predicts all as negative).
- What will be the accuracy of this model?

Look at this table for our model which predict negative all the time:

	<b>Predicted Negative</b>	<b>Predicted Positive</b>
Actual Negative	990 (TN)	0 (FP)
<b>Actual Positive</b>	10 (FN)	0 (TP)

$$Accuracy = \frac{990 + 0}{1000} = 99\%$$

High accuracy, but the model fails to detect any actual cases of cancer!

# Why accuracy can be misleading

- In highly imbalanced datasets (e.g., cancer detection), the **minority class** (positive cases) is often underrepresented.
- A model that always predicts the majority class can still have high accuracy, but poor real-world performance.
- In the cancer detection example, 99% accuracy sounds good, but the model doesn't detect any actual cancer cases.
- We need better metrics to evaluate model performance.

#### Scenario:

- An alarm system can either ring or not ring when a thief is present.
- Let's define the outcomes:
  - True Positive (TP): Alarm rings (correctly) when a thief is present.
  - True Negative (TN): Alarm does not ring (correctly) when no thief is present.
  - False Positive (FP): Alarm rings (incorrectly) when no thief is present (a false alarm).

Performance metrics

000000000000000000

False Negative (FN): Alarm does not ring (incorrectly) when a thief is present (a missed alarm).

	Thief Present	No Thief Present
Alarm Rings	TP	FP
<b>Alarm Does Not Ring</b>	FN	TN

### Performance metrics cont.

- Metrics:
  - Sensitivity (Recall):

Sensitivity = 
$$\frac{TP}{TP + FN}$$

Indicates the ability of the alarm system to correctly identify a thief. It is the proportion of actual positives (thief present) that are correctly identified.

Specificity:

Specificity = 
$$\frac{TN}{TN + FP}$$

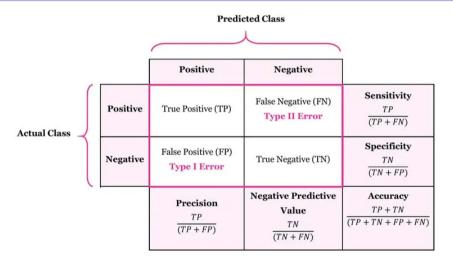

Measures the ability of the alarm system to correctly identify when no thief is present. It is the proportion of actual negatives that are correctly identified.

• Precision:

$$Precision = \frac{TP}{TP + FP}$$

Indicates the accuracy of the alarm when it rings. It is the proportion of times the alarm rang and a thief was indeed present out of all the times the alarm was activated.

### Performance metrics cont.

### A combined measure: F1

- Combined measure: F1 measure
  - allows us to trade off precision and recall
  - · harmonic mean of P and R

$$F = \frac{1}{\frac{1}{2P} + \frac{1}{2R}} = \frac{2PR}{P + R}$$

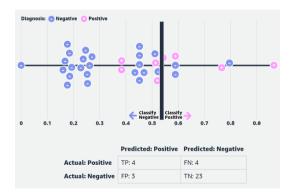

• Harmonic mean of P and R:

$$\frac{1}{F} = \frac{1}{2}(\frac{1}{P} + \frac{1}{R})$$

### Precision/recall/F1

• This website could give you a perfect intuition about precision recall trade-off

Link: https://mlu-explain.github.io/precision-recall/

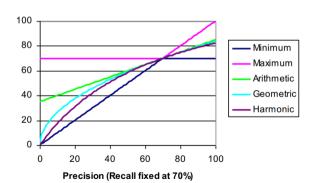

# Why harmonic mean?

- Why don't we use a different mean of P and R as a measure?
  - e.g., the arithmetic mean
- The simple (arithmetic) mean is 50% for "return true for every thing", which is too high.
- Desideratum: Punch really bad performance either on precision or recall
  - · Taking the minimum achieves this.
  - F (harmonic mean) is a kind of **smooth minimum**.

# F1 and other averages

• Harmonic mean is a conservative average. We can view the harmonic mean as a kind of soft minimum

#### **Combined Measures**

### Confusion matrix

- The confusion matrix is a table used to evaluate the performance of a classification model.
- It compares the actual values (true labels) with the predicted values from the model.
- Each **row** of the matrix represents the **actual class**, while each **column** represents the **predicted class**.
- It helps us understand not just how often the model is correct, but also where it makes mistakes.

### Confusion matrix cont.

- Let's consider an image classification task where we classify images into three categories: \*\*Cat\*\*, \*\*Dog\*\*, and \*\*Horse\*\*.
- After training the model, we evaluate its predictions against the actual labels.

	Predicted Cat	Predicted Dog	<b>Predicted Horse</b>
Actual Cat	True Positive (TP)	False Negative (FN)	False Negative (FN)
Actual Dog	False Negative (FN)	True Positive (TP)	False Negative (FN)
Actual Horse	False Negative (FN)	False Negative (FN)	True Positive (TP)

#### Confusion matrix cont.

- Here is an example confusion matrix for a model that classifies images of cats, dogs, and horses:
- We can see that the model classified 8 images of cats correctly, but it classified 1 cat as a dog and 1 cat as a horse (False Negatives).
- Similarly, it made 2 mistakes when predicting dogs and horses.

#### Confusion Matrix

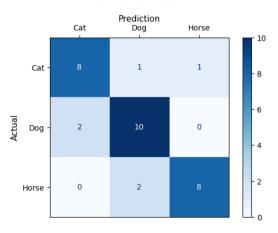

Figure adapted from https://www.geeksforgeek

#### Per class evaluation measures

- **Definition:** For our **confusion matrix C**, each **element C**<sub>ij</sub> denotes the number of samples actually in class i that were put in class j by our classifier.
  - Now we could rewrite our performance metrics with confusion matrix view
- Recall: Fraction of the samples in class *i* classified correctly:

$$\frac{C_{ii}}{\sum_{j} C_{ij}}$$

Precision: Fraction of the samples assigned class i that are actually about class i:

$$\frac{C_{ii}}{\sum_{j} C_{ji}}$$

• Accuracy: Fraction of the samples classified correctly:

$$\frac{\sum_{i} C_{ii}}{\sum_{j} \sum_{i} C_{ij}}$$

## Averaging: macro vs. micro

- We now have an evaluation measure (F1) for one class.
- But we also want a single number that shows aggregate performance over all classes

# Micro- vs. Macro-Averaging

- If we have more than one class, how do we combine multiple performance measures into one quantity?
- Macroaveraging: Compute performance for each class, then average
  - Compute F1 for each of the *C* classes
  - Average these *C* numbers
- Microaveraging: Collect decisions for all classes, aggregate them and then compute measure.
  - Compute TP, FP, FN for each of the *C* classes.
  - Sum these *C* numbers(e.g, all TP to get aggregate TP)
  - Compute F1 for aggregate TP, FP, FN

# Micro- vs. Macro-Averaging: example

### Class 1

## Class 2

#### Micro Ave. Table

	Truth: yes	Truth: no
Classifier: yes	10	10
Classifier: no	10	970

	Truth: yes	Truth:
Classifier: yes	90	10
Classifier: no	10	890

	Truth: yes	Truth:
Classifier: yes	100	20
Classifier: no	20	1860

- Macroaveraged precision: (0.5 + 0.9)/2 = 0.7
- Microaveraged precision: 100/120 = 0.83
- Microaveraged score is dominated by score on common classes

### **AUC-ROC**

- Area Under the Receiver Operating Characteristic Curve
  - ROC (Receiver Operating Characteristic) is a graphical representation of the performance of a binary classification model.
  - It plots the true positive rate (TPR) against the false positive rate (FPR) at different classification thresholds.

#### AUC-ROC cont.

- A high AUC score indicates that the model has good discrimination ability, i.e., it can effectively differentiate between positive and negative instances at different classification thresholds.
- Conversely, a lower AUC-ROC score suggests that the model struggles to differentiate between the two classes.
- AUC ranges from 0 to 1, with 0.5 indicating random guessing and 1 indicating a perfect classifier.

### Model Selection via Cross Validation

#### Cross-Validation

- **Purpose**: Technique for evaluating how well a model generalizes to unseen data.
- How It Works: Split data into k folds; train on k-1 folds and validate on the remaining fold.
- **Repeat Process**: Repeat *k* times, rotating the test fold each time. Average of all scores is the final score of the model.
- Cross-validation reduces overfitting and provides a more reliable estimation of model performance.
- Note that the model must be **retrained** at each iteration to avoid reusing a model that has already seen the test data, ensuring unbiased evaluation.

### K-Fold Cross Validation

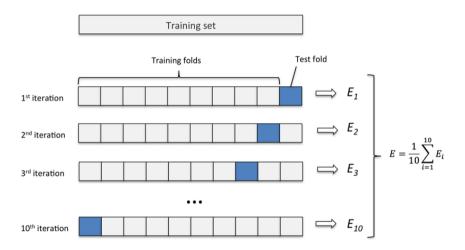

Figure adapted from Introduction to Support Vector Machines and Kernel Methods, J.M. Ashfaque: 🗆 🛌 🕾 🕞 😁 🔍

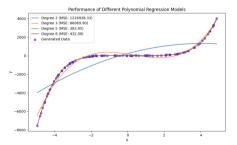

#### • Leave-One-Out Cross-Validation (LOOCV)

- How It Works: Uses a single data point as the validation set (k = 1) and the rest as the training set. Repeat for all data points.
- Properties:
  - No Data Wastage: Every data point is used for both training and validation.
  - High Variance, Low Bias.
  - Computationally Expensive: Requires training the model N times for N data points, making it slow for large datasets.
  - Best for small datasets.

## Cross-Validation for Better Generalization

 Cross-validation is one of the methods used to find the optimal model degree and regularization parameter, ensuring better generalization by minimizing validation error and balancing model complexity.

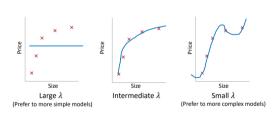

Figure on the right adapted from slides of E.Salehi, Machine Learning course, Sharif University of Technology.

# Cross-Validation for Evaluating Model Performance

- Metrics like accuracy, precision, recall, and F1 score are assessed across different folds.
- Averaging these scores gives a reliable estimate of performance and stability.
- Ensures the model is effective before final testing and use on the test dataset.
- For example, high variance in cross-validation metrics means the model's performance is inconsistent, likely overfitting to specific data subsets.
